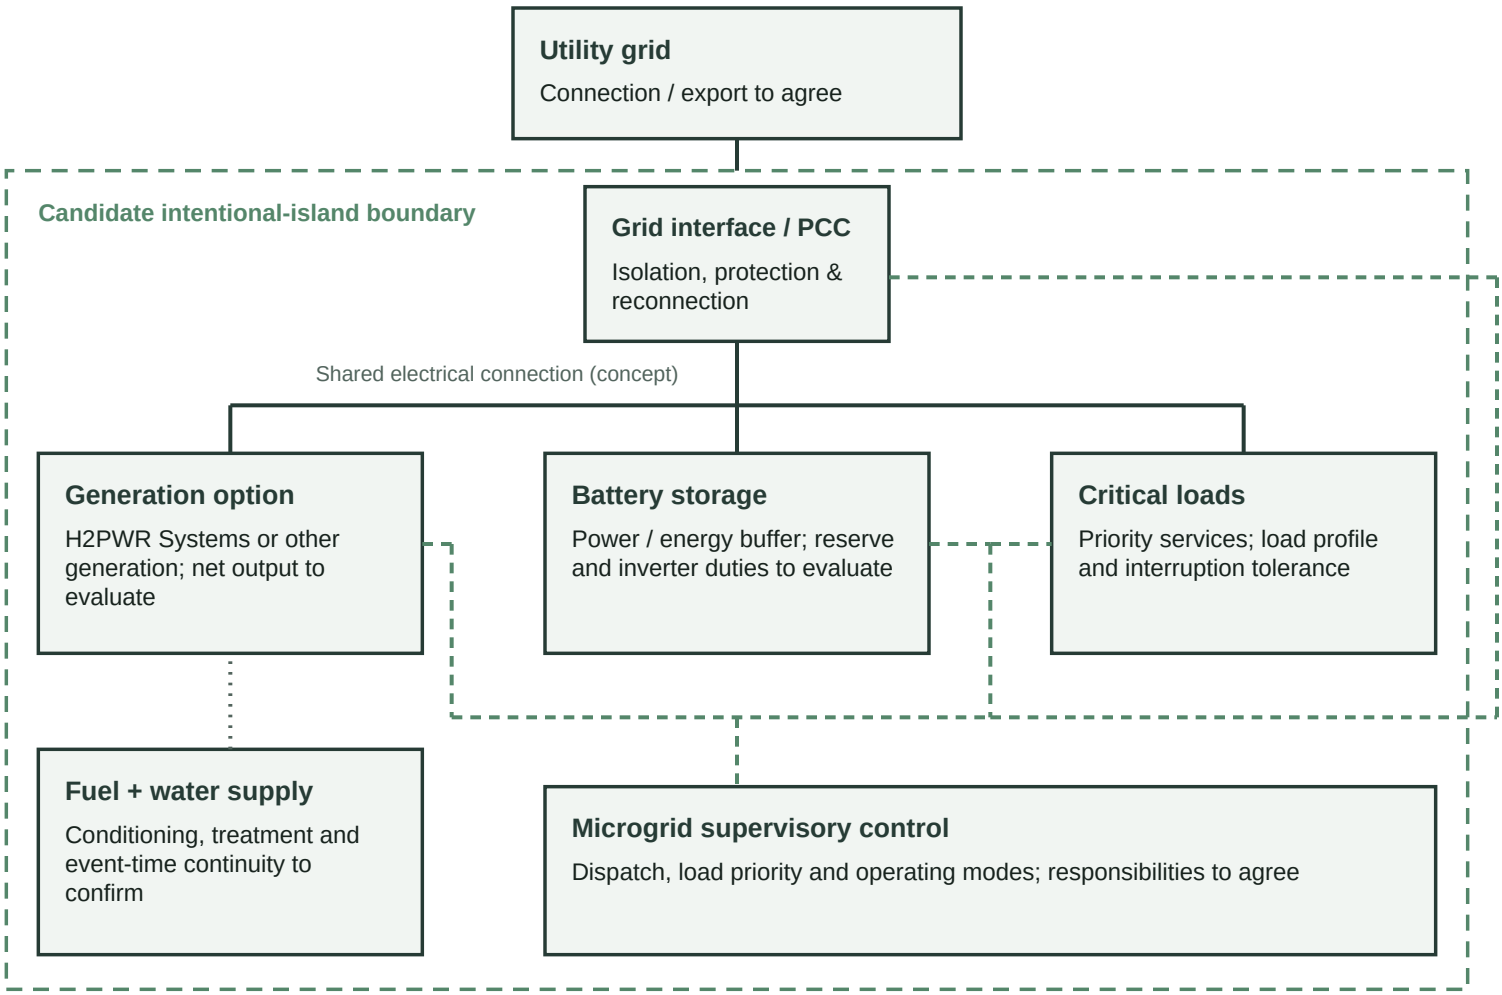
Microgrid resilience: define the operating boundary

Start with the critical loads, then evaluate the generation, storage, supplies and operating responsibilities needed in grid-connected and islanded modes.

Conceptual arrangement and evaluation questions—not measured H2PWR performance or an executable electrical design. No outage duration or equipment readiness is established.



PCC = point of common coupling. Boundary dashes define the candidate island; no power-flow direction or physical scale is implied.

Grid-connected: coordinate exchange and dispatch with the utility.
Islanded: separate from the utility; resource balance, voltage/frequency control and restoration require site-specific engineering.

Resolve the operating questions

Use the concept to scope a utility/site discussion—not to select equipment or set protection and switching procedures.

1. Critical service and operating cases

Which loads must remain supplied, with what interruption tolerance? Obtain time-varying load, motor-start and reactive-power requirements, restoration priority and the outage scenarios to evaluate. Separate required service from any proposed equipment rating.

2. Generation and storage roles

Evaluate H2PWR Systems alongside other generation options. Request configuration-specific net output, auxiliaries, starting behavior, load response and evidence. For storage, evaluate inverter power, usable energy, reserve state of charge and recharge opportunities. Grid-forming, transition support and black start require validation; they are not assumed capabilities.

3. Connection, islanding and restoration

Agree the point of common coupling, export policy and intentional-island boundary with the utility. Study protection, grounding, switching, fault behavior, anti-islanding, utility reclosing, synchronization and reconnection. Establish voltage/frequency regulation in island mode and an approved restoration sequence.

4. Dispatch and control ownership

Assign the utility interface, microgrid dispatch authority and site operating authority. Define who commands resources, load shedding and mode transitions; who maintains local equipment controls; and what happens on faults or loss of communications. H2PWR package controls do not establish complete microgrid-control capability.

5. Fuel, water and supporting services

For the proposed hydrogen-production pathway, confirm feedstock composition, pressure, flow, conditioning and event-time supply. Confirm water quality, flow, treatment, startup demand, storage and loss-of-supply behavior. Include process electricity, auxiliaries, cooling, ventilation and safety provisions; evaluate the complete installed system.

6. Evidence for the resilience decision

Compare load demand with net generation, usable stored energy, reserves, fuel/water continuity and maintenance scenarios. Label design targets, estimates and measured results separately. Ask for integrated-system evidence under the proposed conditions; neither a conceptual layout nor nameplate ratings establish outage endurance.
